MEASURING THE SYSTEMIC IMPORTANCE OF BANKS

Georgios Moratis Athens University of Economics and Business

Plutarchos Sakellaris Athens University of Economics and Business

Abstract

We measure the systemic importance of all banks that issue publicly traded CDS contracts among the world's biggest 150. Systemic importance is captured by the intensity of spillovers of daily CDS movements. Our new empirical tool uses Bayesian VAR to address the dimensionality problem and identifies banks that may trigger instability in the global financial system. For the period January 2008 to June 2017, we find the following: A bank's systemic importance is not adequately captured by its size. European banks have been the main source of global systemic risk with strong interconnections to US banks. For the global system, we identify periods of increased interconnections among banks, during which systemic and idiosyncratic shocks are propagated more intensely via the network. Using principal components analysis, we identify a single dominant factor associated with fluctuations in CDS spreads. Individual banks' exposure to this factor is related to their government's ability to support them and to their retail orientation but not to their size.

JEL classification: E30, E50, E58, E60, G15

Keywords: Macroprudential Policy, Systemic Risk, Financial Markets

Acknowledgements: We would like to thank Heather Gibson, Tryphon Kollintzas, Dimitris Korobilis, Dimitris Malliaropoulos, Petros Mygiakis, Frank Smets and seminar participants at Bank of Greece, University of Crete, University of Birmingham and Athens University of Economics and Business for useful comments. This research was conducted when Georgios Moratis was visiting Bank of Greece on the Bank's programme of cooperation with universities.

1. Introduction

Macroprudential policy entails bank supervision from a system-wide perspective, rather than that of the individual institution. The objective is to limit the risk of system-wide financial crisis as well as to contain the costs to the real economy, if a crisis erupts. In order to ensure that each institution pays for the externality it imposes on the global system, the measures applied to each bank should be calibrated to the systemic importance of each bank. In this paper, we provide a measure of systemic importance of all banks that issue publicly traded CDS contracts among the world's biggest 150 banks, for the period January 2008 to June 2017. We capture systemic importance by the intensity of spillovers of daily CDS movements. This measure captures institutional externalities such as "too big to fail", or "too correlated to fail."

We obtain some strong and, in some respects, surprising results. A bank's systemic importance is not adequately captured by its size. In addition, a considerable number of banks officially designated as GSIBs are not ranked high in terms of our novel measure of systemic importance.¹ Throughout the examined period, European banks have been the main source of global systemic risk with strong interconnections to US banks. Looking at the time dimension for global systemic risk, we identify periods of increased interconnections among banks, during which systemic and idiosyncratic shocks are propagated more intensely via the network. In a complementary but separate approach, we use principal components analysis in order to identify a single dominant factor associated with fluctuations in banks' CDS spreads. Individual banks' exposure to this factor is related to their government's ability to support them and to their retail orientation but not to their size. In particular, regarding the bank-sovereign nexus, our evidence is consistent with fiscally strong sovereigns insulating their large banks from this dominant factor throughout this period.

Our novel measure of bank systemic importance identifies separately the degree of externalities originating in a bank from its vulnerability to the system.

¹ See FSB (2013) for a description of the methodology for assessing the systemic importance of global systemically important banks (GSIBs) and the higher loss absorbency requirements imposed on them.

Externalities are captured by the degree to which a shock experienced by a bank is propagated to each individual bank in the global bank system. Vulnerability is captured by the shocks it receives from each bank in the global system. In particular, we find that more systemically important banks display relatively higher externalities than vulnerability to the global system. This decomposition better allows the macroprudential supervisor to differentiate the "cure" according to the individual bank's systemic "disease". The "cure" usually consists of a combination of capital requirements, quantitative restrictions, and supervisory review actions. Arguably, our decomposition facilitates an improved approach to safeguarding financial stability.

Our methodology is based on two pillars. First, we use market information incorporated in CDS spreads as a reduced-form measure of the linkages among banks.² CDS spreads are a better measure of credit risk than bond spreads, equity returns or other market variables. Second, we use Bayesian VAR to confront the high dimensionality of bank networks. Past work on this topic had to limit attention to a subset of global banks because of the dimensionality problem.³ The closest to our approach is Alter and Beyer (2013), which builds upon the framework of Diebold and Yilmaz (2009, 2011). We deviate from common practice in the literature by removing any market-wide shocks through the inclusion of a set of common external systemic variables. Thus, we allow each bank to become a source of systemic risk after idiosyncratic shocks through spillovers.

The remainder of this document is structured as follows. Section 2 presents the existing literature and section 3 describes the process of measuring systemic risk, the existing frameworks and the motivation. Section 4 presents the methodology and the data, while section 5 presents the results and section 6 concludes.

 $^{^2}$ These linkages may arise from correlated exposures, counterparty relationships or other structural channels.

³ There are two exceptions that address the dimensionality problem using LASSO methods applied to stock return data: Demirer et al. (2017) for the global bank system and Basu et al. (2016) for the U.S. financial system.

2. Relevant literature

Our paper is closely related to four literature strands. First, it is related to studies concerning macroprudential policy. The aim of macroprudential policy is to increase the resilience of individual financial institutions and of the financial system as a whole, by limiting the build-up of vulnerabilities in order to mitigate systemic risk (ECB, 2016). It is also used to smooth-out the financial cycle, driven by fluctuations in credit, leverage and asset prices, which may otherwise result in a pattern of boom and bust (Dell'Ariccia et al., 2013; Elliot et al., 2013; Cerutti et al., 2015). Appropriate policies should be designed toward limiting the ex ante externalities that lead to an excessive build-up of systemic risk, and the ex post externalities that can generate inefficient failures of otherwise sound institutions in a crisis. All in all, macroprudential policy is the usage of primarily prudential tools to limit systemic risk (Crockett, 2000; FSB/IMF/BIS, 2011; IMF 2013).

The literature on macroprudential policy is growing at a fast pace but is still at an early stage and historical experience is thin. The most relevant part of the literature aims at assessing the systemic importance of GSIBs. The most important framework is the one developed by Basel Committee on Banking Supervision (BCBS). The framework compares each bank's activity over twelve indicators and finally assigns a score to each bank. The indicators include the size, the interconnectedness, the substitutability, the complexity and the cross-jurisdictional activity of each bank.

The BCBS methodology has also been used by Financial Stability Board for the identification of GSIBs. This methodology has been transposed in the EU regulatory framework (see Article 131 of the Capital Requirements Directive IV (CRDIV)), which defines global systemically important institutions or G-SIIs. The BCBS/FSB framework for determining systemic risk has some deficiencies. It assigns primal importance to size, as all bank characteristics considered are directly related to size. However, the premise that the biggest banks are the most dangerous ones for financial stability is not necessarily backed by empirical evidence. In addition, the weights assigned to the characteristics are arbitrary. Finally, it does not provide any information on the degree of externalities between a particular systemically important bank and any other one in the system. Our contribution is to use direct observations on credit risk

to measure externalities between any two banks in the global system. In this way, we quantify the degree of danger that any bank may pose to the financial system or parts of it. Our methodology flexibly updates the classification dynamically as new information is obtained.

The second relevant field of literature entails alternative systemic risk rankings for financial institutions. There are many methodologies for calculating the exposure of financial institutions to changes in current economic conditions, how concentrated the risks are among the financial institutions and how closely linked they are with each other. One grouping of methodologies employs price-based systemic risk rankings such as banks' VaR (Adams, Fuss, and Gropp, 2014; White, Kim, and Manganelli, 2015), Δ CoVaR (Adrian and Brunnermeier, 2014; Castro and Ferrari, 2014) and MES (Acharya, Pedersen, Philippon, and Richardson, 2010). These measure the VaR or MES of financial institutions conditional on the entire set of institutions performing poorly.

A second grouping of such metrics incorporates book values as well and includes SRISK (Acharya, Engle, and Richardson, 2012; Brownlees and Engle, 2015), leverage ratio (Fostel and Geanakoplos, 2008; IMF, 2009; Geanakoplos and Pedersen, 2014), and CAPM beta times market capitalization (Benoit, Colliard, Hurlin, and Perignon, 2015). Finally, the distressed insurance premium (DIP) by Huang et al. (2011) measures the insurance premium required to cover distressed losses in the banking system.

These closely related approaches have a key weakness, which is that they do not provide information on the pairwise directional connectedness. In other words, they do not describe externalities between any two banks in the global system. In response to this shortcoming, some papers (see Billio et al, 2012) use Granger causality as a tool to uncover directionality. However, Granger causality is unable to consider contemporaneous movements, control for exogenous variables, quantify intensities of effects, or consider multi-dimensional networks. All these aspects are enabled by our methodology and measure.

A third group of relevant papers deals with the estimation of high-dimensional VAR models. Our approach is closely related to the approach developed by Alter and

Beyer (2013), which is based on the framework of Diebold and Yilmaz (2009, 2011). The high-dimensionality problem had forced research on global bank connectedness to limit analysis to small samples of banks. Needless to say, this is not appropriate when considering bank importance for the global system. A relevant methodology has been recently suggested by Demirer, Diebold, Liu and Yilmaz (2017), who use LASSO methods to shrink, select and estimate the high-dimensional network linking the publicly-traded subset of global banks. In a similar vein, Basu et al. (2017) use Lasso penalized Vector Autoregressive model to estimate a model that leverages a system-wide approach to identify systemically important financial institutions in the U.S. Our distinct approach is to use Bayesian VAR in order to resolve the dimensionality problem.

Finally, our paper relates to studies that apply principal components methods to analyze systemic risk. Billio et al. (2010) suggested that an important symptom of systemic risk is the presence of sudden regime shifts. Giglio et al. (2015) proposed dimension-reduction estimators for constructing systemic risk indexes from the cross section of measures and prove their consistency in a factor model setting. We differ by examining individual bank loadings on the dominant factor associated with fluctuations in bank CDS spreads and determining which observable characteristics are related to these. This approach provides solid empirical basis for using relevant characteristics as indicators to measure systemic importance indirectly.

3. Definition of systemic importance

Systemic risk may originate in an endogenous build-up of financial imbalances possibly associated with a booming financial cycle; large aggregate shocks hitting the economy or the financial system; or contagion effects across markets, intermediaries or infrastructures. Our study focuses on contagion among banks and measures the systemic importance of a bank by the amount of spillovers it receives from and sends to the rest of the banking system. According to Allen et al. (2012) contagion refers to the risk that the failure of one financial institution leads to the default of others through a domino effect in the interbank market, the payment system, or through asset prices. We adopt the "pure-contagion" (Gomez-Puig and Sosvilla Rivero, 2014) definition by controlling only for external common factors through the inclusion of a set of common external systemic risk factors, and assume that each bank could become itself a source of systemic risk as a result of an idiosyncratic shock.

The following example illustrates how we measure the systemic importance of banks (see Figure 1). Assume that there exist three banks. Focusing on bank A as the source of shocks, figure 1 presents the potential impact of an idiosyncratic shock on bank A to bank B and to bank C, separately. Bank A sends a ten-unit shock to B and a seventeen-unit shock to C, a total of 27. Next, we focus on the shocks received by bank A from the other banks in the system. Bank A receives a twenty-one-unit shock from bank B and a five-unit shock from bank C, a total of 26. If we sum the shocks that bank A sends to and receives from the system, we obtain an estimate of the degree of connectedness for bank A. This is a valid measure of bank A's systemic importance. This procedure is repeated in order to calculate the systemic importance of bank B and bank C.

[Figure 1 here]

[Table 1 here]

Table 1 presents the entire picture for all three banks in the system. Shocks emanate from row banks to column banks. Each row shows the contagion effects of an equal-sized impulse to the relevant bank in the first column. In the last column, we aggregate the total externality effects of each row bank. The columns provide the picture of vulnerability of each bank to shocks in different banks. The second to last row is a measure of total vulnerability of a bank to all other banks in the system. It contains the answer to the question: "If all other banks in the system experienced simultaneously an idiosyncratic shock of 100 basis points, what would be the impact on bank X?" In the bottom row, we aggregate the total externality effect and the total vulnerability effect of each bank. In other words, we lump together shocks sent and received by an individual bank as a measure of total individual bank connectedness. In calculating a bank's systemic importance, we assign equal weights to shocks it sends as to shocks it receives, as we are agnostic as to whether one source of systemic instability is more dangerous than the other.

There are two aspects of financial contagion due to a bank's participation in a banking system that are of relevance to regulators: externalities emanating from a bank's failure and individual bank vulnerability to financial contagion. Both components are important for regulators but their importance may not be equal. If they are of equal importance, then the regulator would consider the sum of these two. However, the clear decomposition in Table 1, as well as in our econometric method, allows the regulator to assign different weights in order to capture the appropriate measure of systemic importance.

4. Data and methodology

4.1 Data

We study 77 banks from 19 developed and 7 emerging economies. Our selection procedure is as follows. We started with the list of the world's top 150 banks, in terms of total assets in Q4:2016. Using bank names, we matched 77 banks to CDS prices from Thomson-Reuters Datastream and Bloomberg. CDS spreads cover the period from January 2008 to June 2017 and are at daily frequency. The sample contains all banks that are designated as *"global systemically important banks"* ("GSIB's") by the Basel Committee on Banking Supervision, except for three Chinese banks (Agricultural Bank of China, Bank of China, and Industrial and Commercial Bank of China) and one French bank (Group BPCE). Table 2a (in the Appendix) classifies banks by assets and provides detail on the 77 banks in the sample, such as home-country and total assets, while table 2b (in the Appendix) classifies banks by home-country. We note that 40 out of the 77 banks (52%) in the sample are from Europe while 28 of them (34%) are headquartered in Eurozone members. Tables 3a and 3b (in the Appendix) provide the regional characteristics of the sample.

[Tables 2a, 2b, 3a, 3b here]

4.1.1 Systemic risk factor

We allow for the presence of a global systemic risk factor. This permits us to interpret robustly the results obtained from our model. Longstaff et al. (2011), for instance, has argued that credit risk appears related to global rather than country-specific factors, while Aizenman et al. (2013) has established the importance of international economic factors in the pricing of credit risk. The variables we chose to employ in order to capture global financial risk conditions have been widely used in related studies as control variables (see, among others, De Santis, 2012; Aizenman et al., 2013; Ang and Longstaff, 2011). The global default risk conditions are represented by: the CDX, which is the family of CDS indices covering North America, the VIX volatility index which captures the global capital markets' "fear" condition, and the global liquidity conditions, which is represented by the US 3-month treasury bills. The systemic factor is assumed to affect the endogenous variables contemporaneously. Table 4 contains the variable definitions and Table 5 provides descriptive statistics.

[Tables 4, 5 here]

4.1.2 Bank-specific characteristics

A variety of bank- and country-specific variables are used for identifying the determinants of systemic risk fluctuation over time. The first bank-specific variable is bank size expressed as each bank's total assets (in log). According to BIS (2011a) the larger a bank is, the more likely it is to receive a bailout package. In this sense, we also take into consideration the "too-big-to-fail" (TBTF) issue (Acharya et al., 2013). The second bank-specific variable is the loan-to-asset ratio, which provides information on the bank's retail orientation. Ayadi et al. (2011) and Köhler (2013) suggest that retail-orientated banks appeared to be less risky than other banks during the recent financial crisis. Also, according to Altunbas et al. (2011) the non-interest income over total revenue is considered to be a measure of each bank's diversification, since the less a bank relies on interest income, the less exposed the

bank is to a negative shock. Finally, we include each bank's nonperforming loans over total loans (see Tables 4 and 5).

4.1.3 Country-specific characteristics

It is important to include country-specific factors, since the impact of macroprudential policy might differ depending on the underlying economic conditions of each bank's home country. For example, the impact of shocks may be different for economies that were under stress and hence rely more on rescue packages and foreign financing (IMF 2015a). These economies would not have the same ability to support effectively their banking systems in times of distress. We investigate the role of sovereigns through a bank's home-country *GDP growth*, the *primary surplus over GDP*, and *public debt over GDP*.

4.1 Connectedness matrix

We estimate a VARX model with two lags (p=2) for the endogenous variables and contemporaneous exogenous variables (q=0).

$$Y_{t} = a_{0} + A_{1}Y_{t-1} + A_{2}Y_{t-2} + B_{1}X_{t} + u_{t}$$

The vector of endogenous variables (y) consists of log differences of daily CDS spreads for the 77 banks. By including the exogenous variables, we account for common factors that affect at the same time all bank CDS spreads (Bekaert et al., 2005).

4.2.1 Bayesian VAR

The suggested model has many more parameters than observations, and as a consequence could perform poorly. Researchers working in the relevant literature typically use prior shrinkage on the parameters to overcome such overparametrization concerns. Most flexible Bayesian priors that result in shrinkage of high-dimensional parameter spaces rely on computationally intensive Markov Chain Monte Carlo (MCMC) methods. Their application to recursive forecasting exercises can, as a consequence, be prohibitive or even infeasible. The only exception is the traditional "Minnesota prior", an empirical-Bayes prior which is due to Littermann (1979) and co-authors (see, e.g. Doan, Litterman, and Sims, 1984) and still dominates many applications of VAR models in economics.

The "Minnesota prior" is based on the natural conjugate prior, an idea that has recently been exploited by Banbura, Giannone and Reichlin (2010) and Giannone, Lenza and Primiceri (2012), among others. While this prior allows for an analytical formula for the posterior, there is a cost in terms of flexibility in that *a priori* all VAR equations are treated in the same manner; see Koop and Korobilis (2010) for a further discussion of this aspect of the natural conjugate prior. For computational simplicity we restrict the model to use conjugate prior is (whose posterior has the same distributional family as the prior distribution). This restriction allows for analytical calculation of the Bayesian VAR, rather than simulation-based estimation (*e.g.* the MCMC method). It is also worth noting that the choice of priors does not imply the need for different Bayesian techniques of estimation. Disagreement over the priors may be addressed by post-estimation sensitivity analysis evaluating the robustness of posterior quantities of interest to different prior specifications.

We estimate the coefficients of a VARX(2) for 77 banks using the log differences of each bank's CDS. As we explained above, a key concern of users of Bayesian statistics, and criticism by critics, is the dependence of the posterior distribution on one's prior and for this reason we specify hyperparameters for the prior.

The Bayesian VARX(p,s) model can be written as:

$$y_t = a_0 + \sum_{j=1}^p A_j y_{t-j} + \sum_{i=0}^s \Theta_i^* x_{t-i} + \varepsilon_t$$

where y_t for t = 1,..., T is an $M \times 1$ vector containing observations on M time series variables, εt is an $M \times 1$ vector of errors, α_0 is an $M \times 1$ vector of intercepts and A_j is an $M \times M$ matrix of coefficients. We assume ε_t to be *i.i.d.* N (0, Σ). The prior means for the exogenous coefficients are set to zero.

4.2.2 The connectedness matrix framework

The construction of the diagnostic tool is based on a medium-size Bayesian vector autoregressive model with exogenous variables (Bayesian VARX) that accounts for common global and regional trends, and is able to include even bank-specific characteristics. Then, similar to the framework described by Diebold and Yilmaz (2009, 2012) and the one described by Alter and Beyer (2013), we construct the spillover matrix in order to capture any potential spillovers among banks. This methodology relies on Generalized Forecast Error Variance Decomposition (GFEVD) or on Generalized Impulse Response Functions (GIRF), obtained as shown in Pesaran and Shin (1998). Therefore, we derive Generalized Impulse Response Functions as functions of residuals together with the interdependent coefficients. According to Alter and Beyer (2012), it is of low importance which methodology we select, since they produce qualitatively similar results.

[Table 6 here]

In table 6, each row variable is an origin of unexpected shock. Column variables are the respondents that receive the contagion effects. The bottom right cell represents the total systemic risk index that is defined as the average response per bank in the connectedness matrix and is calculated as the sum of all non-diagonal cells divided by the total number of entities. The expression of total systemic risk as an index makes the overall risk independent of the number of banks in the sample, making comparison between different samples more precise. The potential contagion effects from and to each bank are aggregated on each line and column and represent measures of externalities (To Others) and vulnerability (From Others). The main diagonal values represent the effect of a variable's shock on itself, and they are excluded from any calculations. The possible contagion effects answer the question *"How would bank B evolve in the following period if bank A CDS increased by one unit shock?"*

We use accumulated Impulse Response functions over a 10-step horizon (10days). Not all the banks respond to the shocks within the same period but the majority of the shocks are absorbed within 10 days. Nevertheless, the framework is flexible and it easily adapts to the needs of the study.

5. Empirical results

5.1 Individual bank connectedness

We estimate the connectedness matrix as described in section 4.2.2 for the whole sample period, 1 January 2008 to 31 June 2017, and estimate individual bank connectedness. A striking result in Table 7 is that systemic importance of a bank cannot be adequately captured by its size. According to table 7, the bank that creates the most systemic risk in the system is Intesa Sanpaolo, a medium-sized European bank that is ranked 27th in terms of total assets.

[Table 7 here]

Intesa Sanpaolo has total contagion effects of 1.056, which may be further decomposed into a 0.505 vulnerability score and a 0.551 externalities score. Intesa Sanpaolo's externalities score of 0.551, implies that a one-unit shock to Intesa Sanpaolo's CDS spreads will have an impact of 55.1% to the system. The 0.505 vulnerability score means that simultaneous one-unit shocks to all other banks in the system will affect Intesa Sanpaolo by 50.5%. Among the top 20 most connected banks, we find other smaller banks like BBVA (3rd), Credit Lyonnais (10th), Banca Monte dei Paschi (16th) and Mediobanca (20th). The largest bank in the sample (Bank of China) is ranked 50th in terms of systemic importance.

The existing literature suggests that during crises, large banks behave differently than small or medium-sized banks (e.g. Laeven et al., 2014). This phenomenon could be partially attributed to some common characteristics shared by large banks that are associated with higher levels of risk, namely increased portion of market-based activities, reduced capital adequacy, less stable funding and higher organizational complexity. This literature does not identify a threshold of bank size above which systemic importance kicks in. A major contribution of our paper is to categorize large banks directly for the first time on the basis of their systemic importance.

Table 8 confirms that bank size, while relevant, is by no means adequate in describing a bank's systemic importance. When banks are ranked by our measure of systemic importance, the first quartile comprises 34% of total assets in the system.

However, when the sample is ranked by bank assets, the first quartile comprises 62% of total assets in the system. It is also indicative that only half of GSIBS are classified in the first quartile when ranked by our measure of systemic importance. Clearly, there are bank characteristics other than size that influence bank systemic importance.

The existing frameworks used by regulators and policy makers, such as the BCBS/FSB one, rely heavily on size, either through size-related indicators or size per se, to determine systemic importance. Our results suggest that this may lead to inefficient policies.

[Table 8 here]

Next, we calculate the systemic contribution of each bank in the system as the ratio between the total individual contagion effects and the total contagion in the system:

$$Contribution_{y_i} = \frac{Score_{y_i}}{TSR} * 100$$

Contribution is the individual systemic contribution, *Score* is the total individual contagion effects (externalities and vulnerability) and *TSR* is the total systemic risk in the system. The bank with the highest ranking, *Intesa Sanpaolo*, contributes 2.25% of the total systemic risk, while the bank at the bottom of the list, *Turkiye is bankasi*, has almost zero contribution (see Table 9). This transformation of the initial table allows one to compare rankings among samples that contain a different number of banks.

[Table 9 here]

We define each bank's directional connectedness as the ratio between the *individual externalities* and the *total individual contagion (score)*:

Directionality
$$_{y_i} = \frac{Externalities_{y_i}}{Score_{y_i}} * 100$$
, or

When *directionality* is larger than 50%, the bank's systemic importance is externalities-driven. The separation of banks according to the directionality of shocks allows the supervisor to treat them differently in the context of financial stability. This is important, as externalities and vulnerabilities may have different determinants, different impact on financial stability and may require different macroprudential regulation measures. The results in Table 7 show that the larger banks in the sample emit to the system larger shocks than those they receive, being more extrovert than smaller banks.

Table 10 shows that banks with higher systemic importance tend to have higher externalities ratios. In particular, banks in the first quartile have average individual directionality of 54%, whereas banks in the last quartile average 30%.

[Table 10 here]

5.2 Regional network connectedness

A stark result in Table 7 is that all banks ranked in the first quartile in terms of systemic importance are European. Table 11a displays the geographic distribution of all quartiles. There seems to be strong regional clustering in the different quartiles. For example, the first quartile of systemic importance comprises almost half the European banks in the sample (see Table 11b). It is also noteworthy that 75% of the banks ranked in the first quartile in terms of systemic importance are headquartered in the European.

[Table 11a here]

[Table 11ab here]

Our methodology provides estimates of CDS spillovers between any pair of banks in the system. This allows us to explore further regional effects unveiled by our estimates. We now investigate the flows of contagion between different regions. This will provide a deeper understanding of the degree of connectedness among the different regions (see Table 12).

We focus on four regions, Europe, North America, Asia and Africa. Table 12a presents the externalities of region X to each other region as a percentage of region X's total externalities. The largest portion of shocks generated in the European banking system remains within the region. Of course, European banks are not immune to the banks outside the European Union, but throughout the examined period they have been more vulnerable to shocks that emanated from within. This is consistent with the eurozone crisis being of primal importance. European banks seem to be also the favorite target of shocks emanating from all other world regions. It seems that over the period Jan. 2008 – Jun. 2017 European banks absorbed the majority of shocks that were being transmitted in the global banking system, being by far the most vulnerable banking block. Table 12b displays evidence that 64% of the aggregate shocks that are received by U.S. banks are generated in Europe. Thus, we conclude that the European and U.S. banking sectors have been strongly interconnected and severely exposed to each other.

[Table 12 here]

The highly interconnected banking system, the feedback loop among sovereigns and banks, and the high transmission of contagion effects from one country to the other, put the European banking system in the eye of the storm throughout the examined period.

5.3 National banking system importance

We turn to examining the systemic importance at the national bank level. We calculate the average bank systemic risk for each country in the sample (see Figure 2). The eight leading countries are all in Europe, amplifying the evidence that the majority of turmoil during 2008 – 2017 stemmed from the interior of the European Union and, in particular, from the eurozone.

[Figure 2 here]

French banks suffered from their exposure to the sovereign debt of peripheral euro-area countries and the withdrawal of funds by U.S. money market mutual. Italy and Spain, both of which suffered from banking systems in distress, contributed

heavily as well. This verifies the concerns regarding the systemic importance of relatively smaller banks and their potential effects on the global financial stability. Banks in non-eurozone countries, i.e. Swiss and UK banks are also of great systemic importance. The average systemic importance of German banks places them almost in the middle of the league. Finally, both the Portuguese and especially the Greek banking system appeared to be isolated from the global banking system, while shocks emanating from these banks remained largely within the boundaries of their national banking system.

5.3 Rolling window analysis

5.3.1 Individual Banks

In order to better understand the evolution of systemic risk and how this fluctuated over the whole period we apply rolling-window Bayesian VAR analysis. The length of the window is 340 days and the step is 150 days. Figure 3 presents the evolution of bank systemic importance over the examined period indicating strong co-movement and interconnections among banks. There are periods where the cluster of systemic importance lines shrinks in spread. These are periods when systemic risk becomes more homogeneous across banks.

[Figure 3 here]

We introduce a new metric, which we call *systemic risk range*, defined as the difference between the highest and the lowest systemic importance score in the system (see Figure 4). A lower range signifies more homogeneous systemic importance scores in the global banking system. It is interesting to note that this metric attains its lowest value in the period just after the collapse of Lehman Brothers.

[Figure 4 here]

5.3.2 Global banking system

We move on to analyzing aggregate contagion effects. *Total Systemic risk (TSR)* is defined as the total sum of the off-diagonal entries in the connectedness matrix, or as the sum of the *"from" column* or *"to" row* measures total connectedness.

$$TSR^{H} = \sum_{\substack{i, j=1\\j \neq i}}^{N} IR_{ij}^{H}$$

A slightly different but more interpretable and inclusive way of presenting total systemic risk is the *Total Systemic Risk index (TSRI)* which is defined as the average response per bank in the connectedness matrix and is calculated as the sum of all non-diagonal cells divided by the total number of entities:

$$TSRI = \frac{1}{N} \sum_{i=1}^{N} \sum_{j \neq 1} IR_{y_i \to y_j}$$

Since cumulative IRs lie in the interval [0,1], the index will be bound between 0 and 100. A higher contagion index implies a tightening of the nexus among banks (see Figure 5).

[Figure 5 here]

Total connectedness reached its peak after the collapse of Lehman Brothers. Another important period was associated with the developments in the European banking and sovereign debt markets that shocked some EU member countries until mid-2012. The Greek crisis and then, in early 2011, the inclusion of Italy and Spain to the countries with stressed banking systems pushed total systemic connectedness upwards. After early 2012, the actions taken by the ECB contained system-wide contagion. However, after mid 2015 market concerns about euro area banks' longer-term profitability prospects as well as higher political uncertainty regarding UK membership in the EU and the US election, contributed to the sharp increase in the index. Another major concern for global markets was the crisis in Deutsche Bank as the bank had deep connections to global financial institutions. However, since early 2017 total systemic connectedness has been decreasing substantially.

5.3.3 Rolling window – regional systemic contribution

In this subsection, we concentrate on the European and U.S. banking systems. We track the evolution of the systemic importance of the two regions calculated as the ratio of aggregated systemic importance scores of banks in a region over those in the complete sample. Figure 6 compares the systemic contribution of these regions. The share of systemic risk due to European banks increased dramatically after 2014, while the contribution of U.S. banks started dropping after late 2011 and has remained lower since. The difference between the systemic contribution of European and US banks fluctuates between 40% and 55%. The fact that the share of a region's systemic contribution increases does not necessarily mean that total systemic risk increases as well. The sharp increase in European banking sector's systemic importance starting in early 2014 is probably related to the persistent accumulation of non-performing loans and contagion effects from the Deutsche bank crisis.

[Figure 6 here]

5.4 Principal components analysis

So far in this paper, we used an impulse response methodology to study how one bank's risk contaminates another's. In this section, we depart from these novel measures of systemic importance for banks. Instead, we study contemporaneous comovements in the CDS spreads of banks. We identify factors that make banks move together and observable characteristics that are related to them. We use principal components analysis (PCA), in which movements banks' CDS spreads are decomposed into movements of orthogonal factors of decreasing explanatory power (see Muirhead, 1982 for an exposition of PCA).

PCA produces the decomposition of the variance-covariance matrix of CDS spreads of the 77 banks contained in the sample into the orthogonal matrix of loadings (eigenvector of the correlation matrix of CDS spreads) and the diagonal matrix of eigenvalues. We focus on the first three eigenvalues as they explain most of the variation in the system. When bank CDS spreads co-move more intensely together, these three eigenvalues should explain a larger portion of the total volatility in the system. Therefore, periods, when the first three factors account for larger share of total volatility suggest increased interconnection among banks.

We apply rolling window PCA, where the length of the window is 200 days and the step is 100 days, over the period January 2008 to December 2016 (see Figure 7). The first component accounts for between 30% and 40% of total variance in the observed variables while component 2 and 3 seem to have limited explanatory power and limited variation in that. Consequently, we focus our analysis on the first component. The identification of a single dominant component that determines the fluctuations of CDS spreads is in line with the evidence in Fontana and Scheicher (2010). According to Billio et al. (2012), during periods of distress, fewer components explain a larger part of the volatility in CDS spreads, thus revealing increased systemic risk.

[Figure 7 here]

We now ask the question: Which observable bank and country characteristics are related to the exposure of a bank's CDS movements to the dominant common factor? We run the following cross-sectional regression each year over the period 2008-2016:

$$y_{i} = a + \beta_{1}Assets_{i} + \beta_{2}Loans_{i} + \beta_{3}NPLs_{i} + \beta_{4}NII_{i} + \beta_{5}GDP_{i} + \beta_{6}Surplus_{i} + \beta_{7}Debt_{i} + \varepsilon_{i}$$

yi is bank i's loading on the first component.

[Table 9 here]

The observable bank-specific characteristics we explore are: total value of bank assets (in logs), its retail orientation (total loans/total assets in levels), NPLs/ total loans, and non-interest income / total revenue. We also relate the following homecountry characteristics: GDP growth, primary surplus/GDP, public debt/GDP). The sub-sample used in this regression contains 47 banks that have been matched to bank-specific characteristics.

Table 13 contains the results. Throughout the examined period, retail orientation affects strongly and negatively the banks' loadings in the first component. This indicates that retail-orientated banks have been less exposed to secular movements in the dominant common factor over the decade examined in this paper. Surprisingly, non-performing loans, diversification as well as bank size seem to have an insignificant effect on bank exposure to systemic movements. Regarding country-specific characteristics, a strong result is that the home country's GDP affects strongly and negatively the exposure of banks to systemic risk. This is evidence that, in cases of a distressed sovereign, home banks are less exposed to the common factor. The opposite holds where the sovereign is strongly solvent. In addition, Debt/GDP is negatively and significantly associated with the exposure to systemic risk and it seems that banks with weaker sovereigns have less reliance on the interbank market and are, thus, less affected by global shocks.

[Table 13 here]

6 Conclusions

Macroprudential policy is still in its infancy. Much work is still needed on developing good and timely analysis, effective policy instrument tools, and effective implementation. Our paper makes a contribution on the dimension of analysis and measurement. The key aim of macroprudential policy is to address externalities and spillovers among financial institutions in an effort to safeguard financial stability. These interactions are complex. We provide a tool that clarifies and quantifies these interactions expressing them in a single score. Our measure can guide appropriate macroprudential policies that aim to internalize these externalities. A key conclusion from our study is that a focus on size does not adequately address the systemic importance of banks.

B. Data Definitions and Descriptive Statistics

Variable	Description
Endogenous	
CDS	CDS 5-year spread
Exogenous	
Systemic risk	
CDX	The family of CDS indeces covering North America
VIX	The volatiliy index of S&P 500
US 3-month T Bill	The short-term obligation backed by the Treasury Dept. of the U.S. goverment
Bank-specific	
Size	Total assets
Retail orientation	Total Loans / Total assets
Diversification	Non-interest income / Total revenues
NPLs	Non-performing loans / Total Loans
Country-specific	
GDP	Each bank's home-country GDP growth
Budget Balance	Current Account/GDP
Public Debt	Public Debt/GDP

Note: Data are in levels

Shock\Response	y 1	y_2	To Others		
y1	-	$IR_{y1 \rightarrow y2}$		$IR_{y1 \rightarrow yn}$	$\sum_{j=1}^{N} IR_{y1 \rightarrow yj}, j \neq 1$
<i>y</i> 2	$IR_{y2 \rightarrow y1}$	-		$IR_{y2 \rightarrow yn}$	$\sum_{j=1}^{N} IR_{y2 \to yj}, j \neq 2$
:	:		٠.	:	:
y_n	$IR_{yn \rightarrow y1}$	$IR_{yn \rightarrow y2}$		-	$\sum_{j=1}^{N} IR_{yn \rightarrow yj}, j \neq n$
From Others	$\sum_{j=2}^{N} IR_{yj \to y1}$	$\sum_{j=1}^{N} IR_{yj \rightarrow y2}$	$TSRI = \frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{N} IR_{j_i \to j_j}$		
Score	The sum bet				

Table 6: Contagion/connectedness matrix

Note: Variables in the first column are the impulse origin, while variables on the top row are the respondents to the shock. The impact is bound between 0 and 1. A value of 0.3 means that the response variable would be impacted in the same direction with an intensity of 30% the initial unexpected shock in the impulse variable. The last column presents the aggregated impact sent (To Others) by each row variable and on the bottom row the aggregated spillover received (From Others) by each column variable.

Part B – Global Sample

Table 7 - Panel A continued from previous page

Note: Results concern the period January 2008 – June 2017 and are of daily frequency

	Banks rank	ed by:
Quartile	Systemic Importance	Assets
1st	34%	62%
2nd	33%	22,4%
3rd	18%	10,5%
4th	14%	5,1%

Note: The *systemic importance* column shows the distribution by quartile of total bank system assets when banks are ranked in terms of systemic importance. The *assets* column shows the distribution by quartile of total bank system assets when banks are ranked in terms of assets.

Table 9: Systemic contribution per bank (January 2008 – June 2017)

	Table 9: Systemic contribution per						рапк (January 2008 – June 2017)

20	Mediobanca	1,75	40	Commonwealth Bank	1,28	60	Bank of Ireland	0,81			

Note: Table presents the systemic contribution of each bank in the system as the ratio between the total individual contagion effects and the total contagion in the system

Quartile	Directionality
1st	54%
2nd	53%
3rd	47%
4th	30%

Table 10: Directionality of Bank Systemic Importance

Note: Table presents the average directionality for banks in each quartile, when ranked by systemic importance. Directionality is the ratio between the *individual externalities* and the *total individual contagion*.

Table 11a: Concentration of banks per region

Quartile	Europe	N. America	Asia	Oceania	Africa
1st	100%	-	-	-	-
2nd	25%	40%	25%	10%	-
3rd	50%	10%	30%	10%	-
4th	35%	12%	48%	-	5%

Note: Table presents the regional concentration of banks for each quartile of systemic importance. Banks are ranked by their systemic importance.

Quartile	Europe	N. America	Asia	Oceania	Africa
1st	47%	-	-	-	-
2nd	12%	73%	25%	25%	-
3rd	21%	9%	35%	75%	-
4th	16%	18%	40%	-	100%

Table 11b: Regional concentration as a percentage of total banks per region

Note: The table presents the concentration of banks as a percentage of the total number of banks for each region for each quartile of systemic importance. For instance, 47% of the European banks can be found in the first quartile of systemic importance.

Table 12: Regional Bank Network

	Asia	Europe	N.America	Oceania	Sum
Asia	41%	41%	9%	9%	100%
Europe	16%	69%	9.6%	5.4%	100%
N.America	19.5%	58%	16%	6.5%	100%
Oceania	33%	44.5%	9.5%	12%	100%

Panel A – Externalities of a region as a % of this region's total externalities

Panel B - Vulnerabilities of a region as a % of this region's total vulnerabilities

	Asia	Europe	N.America	Oceania
Asia	28%	10%	13%	21%
Europe	54%	75%	64%	59%
N.America	12%	12%	20%	13%
Oceania	6%	3%	3%	7%
Sum	100%	100%	100%	100%

Note: Panel A presents the *externalities* of region X to each other region as a percentage of region X's total *externalities*. Panel B presents the *vulnerability* of region X to each other region as a percentage of region X's total *vulnerability*.

Table 13: Determinants of each bank's loadings in the first component over the nine periods

Note: ***1%, **5%,*10%. Bank size is each bank's total assets (log). The loan-to-asset ratio (levels) stands for each bank's retail orientation. The non-interest income (levels) over total revenue is considered to be a measure of each bank's diversification. The role of sovereigns is examined through a bank's home-country *GDP growth*, the *primary surplus over GDP (levels)*, and *public debt over GDP (levels)*.

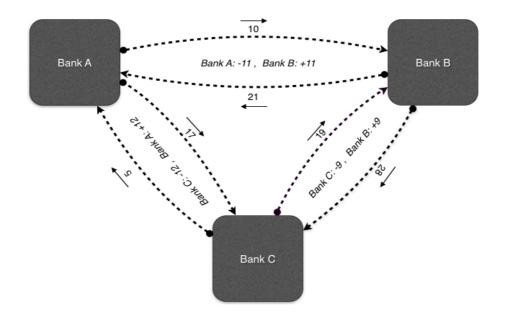

Figure 1: Example of pairwise directional connectedness

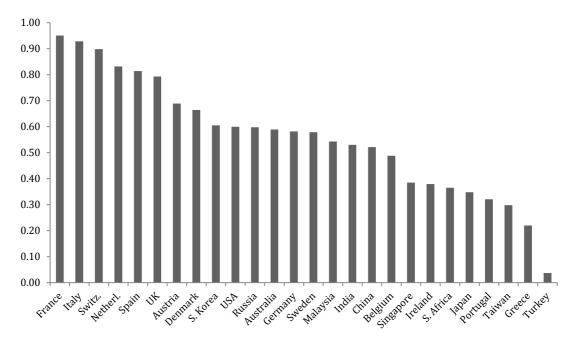

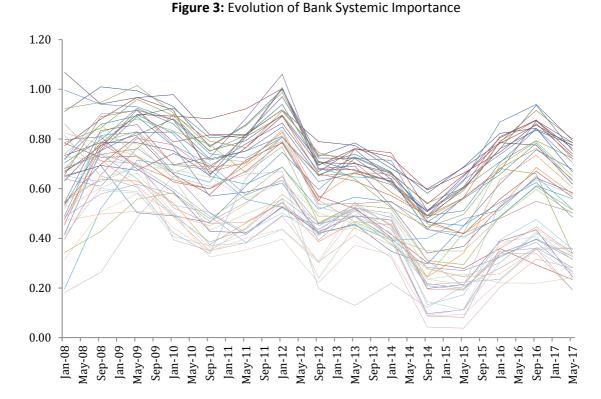

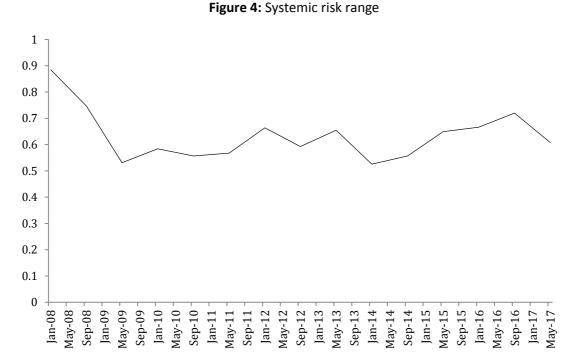

Figure 2: Average systemic risk per bank – Own shocks are excluded

Note: Results cover the period January 2008-June 2017.

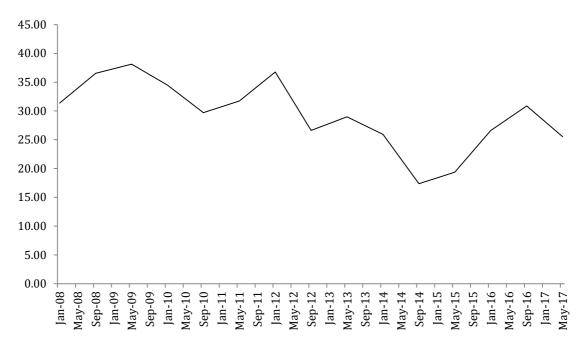

Note: Each line depicts the total systemic risk *(externalities + vulnerability)* for each bank in the sample. The length of the rolling window is 340 days and the step is 150 days.

Note: Systemic risk range is defined as the difference between the highest and the lowest systemic importance score in the system. The length of the window is 340 days and the step is 150 days.

Note: TSRI is defined as the average response per bank in the connectedness matrix. The length of the window is 340 days and the step is 150 days.

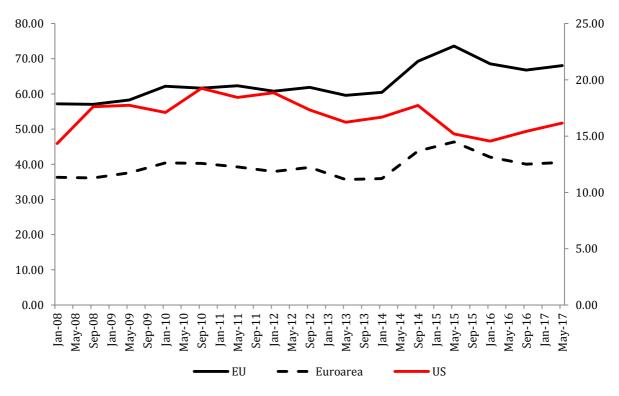

Figure 6: European, US and Euro-area banks' contribution to total systemic risk

Note: Figure presents the ratio of aggregated systemic importance scores of banks in Europe, Eurozone and the U.S. over those in the total sample. US banks' contribution is measured on the right axis.

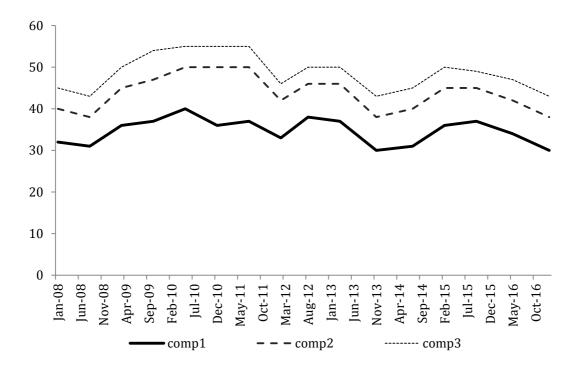

Figure 7: Rolling Principal Components analysis

Note: Figure presents the first three eigenvalues that explain most of the variation in the system over the period 2008-2016. The length of the window is 200 days and the step is 100 days
